56.5 Division on *int*

The following specification of integer division rounds towards minus infinity and is advocated by Donald Knuth. See [5] for an overview and terminology of different possibilities to specify integer division; there division rounding towards minus infinity is named “F-division”.

56.5.1 Basic instantiation

instantiation *int* :: {*normalization-semidom*, *idom-modulo*}
begin

definition *normalize-int* :: $\langle int \Rightarrow int \rangle$
 where [*simp*]: $\langle normalize = (abs :: int \Rightarrow int) \rangle$

definition *unit-factor-int* :: $\langle int \Rightarrow int \rangle$
 where [*simp*]: $\langle unit-factor = (sgn :: int \Rightarrow int) \rangle$

definition *divide-int* :: $\langle int \Rightarrow int \Rightarrow int \rangle$
 where $\langle k \div l = (sgn\ k * sgn\ l * int\ (nat\ |k| \div nat\ |l|)$
 – *of-bool* $(l \neq 0 \wedge sgn\ k \neq sgn\ l \wedge \neg l \div k)$ \rangle

lemma *divide-int-unfold*:
 $\langle (sgn\ k * int\ m) \div (sgn\ l * int\ n) = (sgn\ k * sgn\ l * int\ (m \div n)$
 – *of-bool* $((k = 0 \longleftrightarrow m = 0) \wedge l \neq 0 \wedge n \neq 0 \wedge sgn\ k \neq sgn\ l \wedge \neg n \div m)$ \rangle
 by (*simp add: divide-int-def sgn-mult nat-mult-distrib abs-mult sgn-eq-0-iff ac-simps*)

definition *modulo-int* :: $\langle int \Rightarrow int \Rightarrow int \rangle$

57.6 Generic symbolic computations

The following type class contains everything necessary to formulate a division algorithm in ring structures with numerals, restricted to its positive segments.

```
class linordered-euclidean-semiring-division = linordered-euclidean-semiring +
  fixes divmod ::  $\langle \text{num} \Rightarrow \text{num} \Rightarrow 'a \times 'a \rangle$ 
  and divmod-step ::  $\langle 'a \Rightarrow 'a \times 'a \Rightarrow 'a \times 'a \rangle$  — These are conceptual definitions
  but force generated code to be monomorphic wrt. particular instances of this class
  which yields a significant speedup.
  assumes divmod-def:  $\langle \text{divmod } m \ n = (\text{numeral } m \ \text{div} \ \text{numeral } n, \text{numeral } m \ \text{mod} \ \text{numeral } n) \rangle$ 
  and divmod-step-def [simp]:  $\langle \text{divmod-step } l \ (q, r) =$ 
    (if euclidean-size l  $\leq$  euclidean-size r then  $(2 * q + 1, r - l)$ 
    else  $(2 * q, r)$ )  $\rangle$  — This is a formulation of one step (referring to one
    digit position) in school-method division: compare the dividend at the current digit
    position with the remainder from previous division steps and evaluate accordingly.
begin
```

```
lemma fst-divmod:
   $\langle \text{fst } (\text{divmod } m \ n) = \text{numeral } m \ \text{div} \ \text{numeral } n \rangle$ 
by (simp add: divmod-def)
```

```
lemma snd-divmod:
   $\langle \text{snd } (\text{divmod } m \ n) = \text{numeral } m \ \text{mod} \ \text{numeral } n \rangle$ 
by (simp add: divmod-def)
```

Following a formulation of school-method division. If the divisor is smaller than the dividend, terminate. If not, shift the dividend to the right until termination occurs and then reiterate single division steps in the opposite direction.

```
lemma divmod-divmod-step:
   $\langle \text{divmod } m \ n = (\text{if } m < n \text{ then } (0, \text{numeral } m)$

61.5 Intervals of natural numbers

61.5.1 The Constant *lessThan*

lemma $\text{lessThan-0 } [simp]: \text{lessThan } (0::\text{nat}) = \{\}$
by (*simp add: lessThan-def*)

lemma $\text{lessThan-Suc}: \text{lessThan } (\text{Suc } k) = \text{insert } k (\text{lessThan } k)$
by (*simp add: lessThan-def less-Suc-eq, blast*)

The following proof is convenient in induction proofs where new elements get indices at the beginning. So it is used to transform $\{\dots < \text{Suc } n\}$ to \emptyset and $\{\dots < n\}$.

lemma $\text{zero-notin-Suc-image } [simp]: 0 \notin \text{Suc } ` A$
by *auto*

lemma $\text{lessThan-Suc-eq-insert-0}: \{\dots < \text{Suc } n\} = \text{insert } 0 (\text{Suc } ` \{\dots < n\})$
by (*auto simp: image-iff less-Suc-eq-0-disj*)

lemma $\text{lessThan-Suc-atMost}: \text{lessThan } (\text{Suc } k) = \text{atMost } k$
by (*simp add: lessThan-def atMost-def less-Suc-eq-le*)

lemma *atMost-Suc-eq-insert-0*: $\{.. \text{Suc } n\} = \text{insert } 0 (\text{Suc } \{.. n\})$
unfolding *lessThan-Suc-atMost*[*symmetric*] *lessThan-Suc-eq-insert-0*[*of Suc n*]
..

lemma *UN-lessThan-UNIV*: $(\bigcup m::\text{nat}. \text{lessThan } m) = \text{UNIV}$
by *blast*

61.5.2 The Constant *greaterThan*

lemma *greaterThan-0*: $\text{greaterThan } 0 = \text{range Suc}$
unfolding *greaterThan-def*
by (*blast dest: gr0-conv-Suc [THEN iffD1]*)

lemma *greaterThan-Suc*: $\text{greaterThan } (\text{Suc } k) = \text{greaterThan } k - \{\text{Suc } k\}$
unfolding *greaterThan-def*
by (*auto elim: linorder-neqE*)

lemma *INT-greaterThan-UNIV*: $(\bigcap m::\text{nat}. \text{greaterThan } m) = \{\}$
by *blast*

61.5.3 The Constant *atLeast*

lemma *atLeast-0* [*simp*]: $\text{atLeast } (0::\text{nat}) = \text{UNIV}$
by (*unfold atLeast-def UNIV-def, simp*)

lemma *atLeast-Suc*: $\text{atLeast } (\text{Suc } k) = \text{atLeast } k - \{k\}$
unfolding *atLeast-def* **by** (*auto simp: order-le-less Suc-le-eq*)

lemma *atLeast-Suc-greaterThan*: $\text{atLeast } (\text{Suc } k) = \text{greaterThan } k$
by (*auto simp add: greaterThan-def atLeast-def less-Suc-eq-le*)

lemma *UN-atLeast-UNIV*: $(\bigcup m::\text{nat}. \text{atLeast } m) = \text{UNIV}$
by *blast*

61.5.4 The Constant *atMost*

lemma *atMost-0* [*simp*]: $\text{atMost } (0::\text{nat}) = \{0\}$
by (*simp add: atMost-def*)

lemma *atMost-Suc*: $\text{atMost } (\text{Suc } k) = \text{insert } (\text{Suc } k) (\text{atMost } k)$
unfolding *atMost-def* **by** (*auto simp add: less-Suc-eq order-le-less*)

lemma *UN-atMost-UNIV*: $(\bigcup m::\text{nat}. \text{atMost } m) = \text{UNIV}$
by *blast*

61.5.5 The Constant *atLeastLessThan*

The orientation of the following 2 rules is tricky. The lhs is defined in terms of the rhs. Hence the chosen orientation makes sense in this theory — the

reverse orientation complicates proofs (eg nontermination). But outside, when the definition of the lhs is rarely used, the opposite orientation seems preferable because it reduces a specific concept to a more general one.

lemma *atLeast0LessThan* [code-abbrev]: $\{0::nat..<n\} = \{..<n\}$
by (*simp add: lessThan-def atLeastLessThan-def*)

lemma *atLeast0AtMost* [code-abbrev]: $\{0..n::nat\} = \{..n\}$

syntax-consts

-from-to-sum -from-upto-sum -upt-sum -upto-sum == sum

translations

$\sum_{x=a..b} t == CONST\ sum\ (\lambda x. t)\ \{a..b\}$

$\sum_{x=a..<b} t == CONST\ sum\ (\lambda x. t)\ \{a..<b\}$

$$\begin{aligned}\sum_{i \leq n}. t &== \text{CONST sum } (\lambda i. t) \{..n\} \\ \sum_{i < n}. t &== \text{CONST sum } (\lambda i. t) \{..<n\}\end{aligned}$$

The above introduces some pretty alternative syntaxes for summation over intervals:

Old	New	L ^A T _E X
$\sum_{x \in \{a..b\}}. e$	$\sum x = a..b. e$	$\sum_{x=a}^b e$
$\sum_{x \in \{a..<b\}}. e$	$\sum x = a..<b. e$	$\sum_{x=a}^{<b} e$
$\sum_{x \in \{..b\}}. e$	$\sum x \leq b. e$	$\sum_{x \leq b} e$
$\sum_{x \in \{..<b\}}. e$	$\sum x < b. e$	$\sum_{x < b} e$

The left column shows the term before introduction of the new syntax, the middle column shows the new (default) syntax, and the right column shows a special syntax. The latter is only meaningful for latex output and has to be activated explicitly by setting the print mode to *latex-sum* (e.g. via *mode = latex-sum* in antiquotations). It is not the default L^AT_EX output because it only works well with italic-style formulae, not tt-style.

Note that for uniformity on *nat* it is better to use $\sum x = 0..<n. e$ rather than $\sum x < n. e$: *sum* may not provide all lemmas available for $\{m..<n\}$ also in the special form for $\{..<n\}$.

This congruence rule should be used for sums over intervals as the standard theorem *sum.cong* does not work well with the simplifier who adds the unsimplified premise $x \in B$ to the context.

63.2 Triggers for quantifier instantiation

Some SMT solvers support patterns as a quantifier instantiation heuristics. Patterns may either be positive terms (tagged by "pat") triggering quantifier instantiations – when the solver finds a term matching a positive pattern, it instantiates the corresponding quantifier accordingly – or negative terms (tagged by "nopat") inhibiting quantifier instantiations. A list of patterns of the same kind is called a multipattern, and all patterns in a multipattern are considered conjunctively for quantifier instantiation. A list of multipatterns is called a trigger, and their multipatterns act disjunctively during quantifier instantiation. Each multipattern should mention at least all quantified variables of the preceding quantifier block.

63.3 Higher-order encoding

Application is made explicit for constants occurring with varying numbers of arguments. This is achieved by the introduction of the following constant.

definition *fun-app* :: 'a \Rightarrow 'a **where** *fun-app* *f* = *f*

Some solvers support a theory of arrays which can be used to encode higher-order functions. The following set of lemmas specifies the properties of such (extensional) arrays.

63.5 Integer division and modulo for Z3

The following Z3-inspired definitions are overspecified for the case where $l = 0$. This Schönheitsfehler is corrected in the *div-as-z3div* and *mod-as-z3mod* theorems.

definition *z3div* :: $\text{int} \Rightarrow \text{int} \Rightarrow \text{int}$ **where**
 $\text{z3div } k l = (\text{if } l \geq 0 \text{ then } k \text{ div } l \text{ else } -(k \text{ div } -l))$

definition *z3mod* :: $\text{int} \Rightarrow \text{int} \Rightarrow \text{int}$ **where**
 $\text{z3mod } k l = k \text{ mod } (\text{if } l \geq 0 \text{ then } l \text{ else } -l)$

lemma *div-as-z3div*:
 $\forall k l. k \text{ div } l = (\text{if } l = 0 \text{ then } 0 \text{ else if } l > 0 \text{ then } \text{z3div } k l \text{ else } \text{z3div } (-k) (-l))$

by (*simp add: z3div-def*)

lemma *mod-as-z3mod*:

$\forall k\ l. k \bmod l = (\text{if } l = 0 \text{ then } k \text{ else if } l > 0 \text{ then } z3mod\ k\ l \text{ else } - z3mod\ (-k) (-l))$

by (*simp add: z3mod-def*)

63.8 Configuration

The current configuration can be printed by the command *smt-status*, which shows the values of most options.

63.9 General configuration options

The option *smt-solver* can be used to change the target SMT solver. The possible values can be obtained from the *smt-status* command.

declare $[[\text{smt-solver} = \text{z3}]]$

Since SMT solvers are potentially nonterminating, there is a timeout (given in seconds) to restrict their runtime.

declare $[[\text{smt-timeout} = 0]]$

SMT solvers apply randomized heuristics. In case a problem is not solvable by an SMT solver, changing the following option might help.

declare $[[\text{smt-random-seed} = 1]]$

In general, the binding to SMT solvers runs as an oracle, i.e., the SMT solvers are fully trusted without additional checks. The following option can cause the SMT solver to run in proof-producing mode, giving a checkable certificate. This is currently implemented only for veriT and Z3.

declare $[[\text{smt-oracle} = \text{false}]]$

Each SMT solver provides several command-line options to tweak its behaviour. They can be passed to the solver by setting the following options.

declare $[[\text{cvc4-options} =]]$

declare $[[\text{cvc5-options} =]]$

declare $[[\text{cvc5-proof-options} = \text{--proof-format-mode=alethe --proof-granularity=dsl-rewrite}]]$

declare $[[\text{verit-options} =]]$

declare $[[\text{z3-options} =]]$

The SMT method provides an inference mechanism to detect simple triggers in quantified formulas, which might increase the number of problems solvable by SMT solvers (note: triggers guide quantifier instantiations in the SMT solver). To turn it on, set the following option.

declare $[[\text{smt-infer-triggers} = \text{false}]]$

Enable the following option to use built-in support for datatypes, codatatypes, and records in CVC4 and cvc5. Currently, this is implemented only in oracle mode.

declare `[[cvc-extensions = false]]`

Enable the following option to use built-in support for div/mod, datatypes, and records in Z3. Currently, this is implemented only in oracle mode.

declare `[[z3-extensions = false]]`

63.10 Certificates

By setting the option *smt-certificates* to the name of a file, all following applications of an SMT solver are cached in that file. Any further application of the same SMT solver (using the very same configuration) re-uses the cached certificate instead of invoking the solver. An empty string disables caching certificates.

The filename should be given as an explicit path. It is good practice to use the name of the current theory (with ending *.certs* instead of *.thy*) as the certificates file. Certificate files should be used at most once in a certain theory context, to avoid race conditions with other concurrent accesses.

declare `[[smt-certificates =]]`

The option *smt-read-only-certificates* controls whether only stored certificates should be used or invocation of an SMT solver is allowed. When set to *true*, no SMT solver will ever be invoked and only the existing certificates found in the configured cache are used; when set to *false* and there is no cached certificate for some proposition, then the configured SMT solver is invoked.

declare `[[smt-read-only-certificates = false]]`

63.11 Tracing

The SMT method, when applied, traces important information. To make it entirely silent, set the following option to *false*.

declare `[[smt-verbose = true]]`

For tracing the generated problem file given to the SMT solver as well as the returned result of the solver, the option *smt-trace* should be set to *true*.

declare `[[smt-trace = false]]`

63.12 Schematic rules for Z3 proof reconstruction

Several proof rules of Z3 are not very well documented. There are two lemma groups which can turn failing Z3 proof reconstruction attempts into succeeding ones: the facts in *z3-rule* are tried prior to any implemented reconstruction procedure for all uncertain Z3 proof rules; the facts in *z3-simp* are

only fed to invocations of the simplifier when reconstructing theory-specific proof steps.

```

n-lists 0 xs = [] |
n-lists (Suc n) xs = concat (map (λys. map (λy. y # ys) xs) (n-lists n xs))

```

hide-const (open) *n-lists*

```

function splice :: 'a list ⇒ 'a list ⇒ 'a list where
splice [] ys = ys |
splice (x#xs) ys = x # splice ys xs
by pat-completeness auto

```

termination

```

by(relation measure(λ(xs,ys). size xs + size ys)) auto

```

function shuffles **where**

```

shuffles [] ys = {ys}
| shuffles xs [] = {xs}
| shuffles (x # xs) (y # ys) = (#) x ‘ shuffles xs (y # ys) ∪ (#) y ‘ shuffles (x #
xs) ys
by pat-completeness simp-all
termination by lexicographic-order

```

Use only if you cannot use *Min* instead:

```

fun min-list :: 'a::ord list ⇒ 'a where
min-list (x # xs) = (case xs of [] ⇒ x | - ⇒ min x (min-list xs))

```

Returns first minimum:

```

fun arg-min-list :: ('a ⇒ ('b::linorder)) ⇒ 'a list ⇒ 'a where
arg-min-list f [x] = x |
arg-min-list f (x#y#zs) = (let m = arg-min-list f (y#zs) in if f x ≤ f m then x
else m)

```

Figure 1 shows characteristic examples that should give an intuitive understanding of the above functions.

The following simple sort(ed) functions are intended for proofs, not for efficient implementations.

A sorted predicate w.r.t. a relation:

```

fun sorted-wrt :: ('a ⇒ 'a ⇒ bool) ⇒ 'a list ⇒ bool where
sorted-wrt P [] = True |
sorted-wrt P (x # ys) = ((∀ y ∈ set ys. P x y) ∧ sorted-wrt P ys)

```

A class-based sorted predicate:

```

context linorder
begin

```

```

abbreviation sorted :: 'a list ⇒ bool where
sorted ≡ sorted-wrt (≤)

```

```

66.1.1 List comprehension

Input syntax for Haskell-like list comprehension notation. Typical example: $[(x,y). x \leftarrow xs, y \leftarrow ys, x \neq y]$, the list of all pairs of distinct elements from xs and ys . The syntax is as in Haskell, except that $|$ becomes a dot (like in Isabelle’s set comprehension): $[e. x \leftarrow xs, \dots]$ rather than $[e \mid x \leftarrow xs, \dots]$.

The qualifiers after the dot are

generators $p \leftarrow xs$, where p is a pattern and xs an expression of list type,
or

guards b , where b is a boolean expression.

Just like in Haskell, list comprehension is just a shorthand. To avoid misunderstandings, the translation into desugared form is not reversed upon output. Note that the translation of $[e. x \leftarrow xs]$ is optimized to $\text{map } (\lambda x. e) xs$.

It is easy to write short list comprehensions which stand for complex expressions. During proofs, they may become unreadable (and mangled). In such cases it can be advisable to introduce separate definitions for the list comprehensions in question.

66.3.3 Sorting functions

Currently it is not shown that *sort* returns a permutation of its input because the nicest proof is via multisets, which are not part of Main. Alternatively one could define a function that counts the number of occurrences of an element in a list and use that instead of multisets to state the correctness property.

66.3.5 sorted-key-list-of-set

This function maps (finite) linearly ordered sets to sorted lists. The linear order is obtained by a key function that maps the elements of the set to a type that is linearly ordered. Warning: in most cases it is not a good idea to convert from sets to lists but one should convert in the other direction (via *set*).

Note: this is a generalisation of the older *sorted-list-of-set* that is obtained by setting the key function to the identity. Consequently, new theorems should be added to the locale below. They should also be aliased to more convenient names for use with *sorted-list-of-set* as seen further below.

definition (in *linorder*) *sorted-key-list-of-set* :: (*'b* \Rightarrow *'a*) \Rightarrow *'b set* \Rightarrow *'b list*
where *sorted-key-list-of-set* *f* \equiv *folding-on.F* (*insert-key* *f*) []

locale *folding-insert-key* = *lo?*: *linorder* *less-eq* :: *'a* \Rightarrow *'a* \Rightarrow *bool* *less*

66.4.2 Lexicographic Ordering

Classical lexicographic ordering on lists, ie. "a" < "ab" < "b". This ordering does *not* preserve well-foundedness. Author: N. Voelker, March 2005.

definition *lexord* :: ('a × 'a) set \Rightarrow ('a list × 'a list) set **where**
lexord $r = \{(x, y). \exists a \ v. y = x @ a \# v \vee$
 $(\exists u \ a \ b \ v \ w. (a, b) \in r \wedge x = u @ (a \# v) \wedge y = u @ (b \# w))\}$

lemma *lexord-Nil-left* [*simp*]: $([], y) \in \text{lexord } r = (\exists a \ x. y = a \# x)$
by (*unfold lexord-def, induct-tac y, auto*)

lemma *lexord-Nil-right* [*simp*]: $(x, []) \notin \text{lexord } r$
by (*unfold lexord-def, induct-tac x, auto*)

lemma *lexord-cons-cons* [*simp*]:
 $(a \# x, b \# y) \in \text{lexord } r \longleftrightarrow (a, b) \in r \vee (a = b \wedge (x, y) \in \text{lexord } r)$ (**is** ?*lhs* = ?*rhs*)

66.7 Code generation

66.7.1 Counterparts for set-related operations

context
begin

qualified definition *member* :: $\langle 'a \text{ list} \Rightarrow 'a \Rightarrow \text{bool} \rangle$ — only for code generation
where *member-iff* [*code-abbrev*, *simp*]: $\langle \text{member } xs \ x \longleftrightarrow x \in \text{set } xs \rangle$

Use *member* only for generating executable code. Otherwise use $x \in \text{set } xs$ instead — it is much easier to reason about.

qualified lemma *member-code* [*code*, *no-atp*]:
 $\langle \text{member } [] \ y \longleftrightarrow \text{False} \rangle$
 $\langle \text{member } (x \# xs) \ y \longleftrightarrow x = y \vee \text{member } xs \ y \rangle$
by *auto*

qualified lemma *Collect-member* [*code-unfold*, *no-atp*]: — make preprocessor setup
confluent
 $\langle \{x. \text{List.member } xs \ x \wedge P \ x\} = \text{Set.filter } P \ (\text{set } xs) \rangle$
by *simp*

qualified lemma *Collect-pair-member* [*code-unfold*, *no-atp*]: — make preprocessor
setup confluent
 $\langle \{(x, y). \text{List.member } xs \ (x, y) \wedge P \ x \ y\} = \text{Set.filter } (\lambda(x, y). P \ x \ y) \ (\text{set } xs) \rangle$
by *auto*

qualified lemma *Collect-triple-member* [*code-unfold*, *no-atp*]: — make preproces-
sor setup confluent
 $\langle \{(x, y, z). \text{List.member } xs \ (x, y, z) \wedge P \ x \ y \ z\} = \text{Set.filter } (\lambda(x, y, z). P \ x \ y \ z) \ (\text{set } xs) \rangle$
by *auto*

end

lemma *list-all-iff* [*code-abbrev*]:
 $\langle \text{list-all } P \ xs \longleftrightarrow \text{Ball } (\text{set } xs) \ P \rangle$
by (*simp add: list.pred-set*)

definition *list-ex* :: $\langle ('a \Rightarrow \text{bool}) \Rightarrow 'a \text{ list} \Rightarrow \text{bool} \rangle$
where *list-ex-iff* [*code-abbrev*]: $\langle \text{list-ex } P \ xs \longleftrightarrow \text{Bex } (\text{set } xs) \ P \rangle$

definition *list-ex1* :: $\langle ('a \Rightarrow \text{bool}) \Rightarrow 'a \text{ list} \Rightarrow \text{bool} \rangle$
where *list-ex1-iff* [*code-abbrev*]: $\langle \text{list-ex1 } P \ xs \longleftrightarrow \text{Set.can-select } P \ (\text{set } xs) \rangle$

Usually you should prefer $\forall x \in \text{set } xs, \exists x \in \text{set } xs$ and $\exists !x. x \in \text{set } xs \wedge$ - over *list-all*, *list-ex* and *list-ex1* in specifications.

lemma *list-all-Nil-iff* [*code*, *no-atp*]:
 $\langle \text{list-all } P \ [] \longleftrightarrow \text{True} \rangle$

```

We want the bitwise operations to bind slightly weaker than + and −.

Logically, *push-bit*, *drop-bit* and *take-bit* are just aliases; having them as separate operations makes proofs easier, otherwise proof automation would fiddle with concrete expressions $(2::'a)^n$ in a way obfuscating the basic algebraic relationships between those operations.

For the sake of code generation operations are specified as definitional class operations, taking into account that specific instances of these can be implemented differently wrt. code generation.

68.11 Key ideas of bit operations

When formalizing bit operations, it is tempting to represent bit values as explicit lists over a binary type. This however is a bad idea, mainly due to the inherent ambiguities in representation concerning repeating leading bits.

Hence this approach avoids such explicit lists altogether following an algebraic path:

- Bit values are represented by numeric types: idealized unbounded bit values can be represented by type *int*, bounded bit values by quotient types over *int*.
- (A special case are idealized unbounded bit values ending in 0 which can be represented by type *nat* but only support a restricted set of operations).
- From this idea follows that
 - multiplication by 2 is a bit shift to the left and
 - division by 2 is a bit shift to the right.
- Concerning bounded bit values, iterated shifts to the left may result in eliminating all bits by shifting them all beyond the boundary. The property $2^n \neq 0$ represents that *n* is not beyond that boundary.
- The projection on a single bit is then $\text{bit } a \text{ } n = \text{odd } (a \text{ div } 2^n)$.
- This leads to the most fundamental properties of bit values:
 - Equality rule: $(\bigwedge n. \text{possible-bit TYPE(int)} \text{ } n \implies \text{bit } a \text{ } n = \text{bit } b \text{ } n) \implies a = b$

- Induction rule: $\llbracket \bigwedge a. a \text{ div } 2 = a \implies P \ a; \bigwedge a \ b. \llbracket P \ a; (\text{of-bool } b + 2 * a) \text{ div } 2 = a \rrbracket \implies P \ (\text{of-bool } b + 2 * a) \rrbracket \implies P \ a$
- Typical operations are characterized as follows:
 - Singleton n th bit: 2^n
 - Bit mask upto bit n : $\text{mask } n = 2^n - 1$
 - Left shift: $\text{push-bit } n \ a = a * 2^n$
 - Right shift: $\text{drop-bit } n \ a = a \text{ div } 2^n$
 - Truncation: $\text{take-bit } n \ a = a \text{ mod } 2^n$
 - Negation: $\text{bit } (\text{NOT } a) \ n = (\text{possible-bit } \text{TYPE}(\text{int}) \ n \wedge \neg \text{bit } a \ n)$
 - And: $\text{bit } (a \ \text{AND } b) \ n = (\text{bit } a \ n \wedge \text{bit } b \ n)$
 - Or: $\text{bit } (a \ \text{OR } b) \ n = (\text{bit } a \ n \vee \text{bit } b \ n)$
 - Xor: $\text{bit } (a \ \text{XOR } b) \ n = (\text{bit } a \ n \neq \text{bit } b \ n)$
 - Set a single bit: $\text{set-bit } n \ a = a \ \text{OR } \text{push-bit } n \ 1$
 - Unset a single bit: $\text{unset-bit } n \ a = a \ \text{AND } \text{NOT } (\text{push-bit } n \ 1)$
 - Flip a single bit: $\text{flip-bit } n \ a = a \ \text{XOR } \text{push-bit } n \ 1$
 - Signed truncation, or modulus centered around 0: $\text{signed-take-bit } n \ a = \text{take-bit } n \ a \ \text{OR } \text{of-bool } (\text{bit } a \ n) * \text{NOT } (\text{mask } n)$
 - Bit concatenation: $\text{concat-bit } n \ k \ l = \text{take-bit } n \ k \ \text{OR } \text{push-bit } n \ l$
 - (Bounded) conversion from and to a list of bits: $\text{horner-sum of-bool } 2 \ (\text{map } (\text{bit } a) \ [0..<n]) = \text{take-bit } n \ a$

```

Function update syntax $f(x := y, \dots)$ is extended with $x \mapsto y$, which is short for $x := \text{Some } y. :=$ and \mapsto can be mixed freely. The syntax $[x \mapsto y, \dots]$ is short for $\text{Map.empty}(x \mapsto y, \dots)$ but must only contain \mapsto , not $:=$, because $[x:=y]$ clashes with the list update syntax $xs[i:=x]$.

nonterminal *maplet* and *maplets*

open-bundle *maplet-syntax*

73.1 Strings as list of bytes

When modelling strings, we follow the approach given in <https://utf8everywhere.org/>:

- Strings are a list of bytes (8 bit).
- Byte values from 0 to 127 are US-ASCII.
- Byte values from 128 to 255 are uninterpreted blobs.

73.1.1 Bytes as datatype

```
datatype char =
```

```
  Char (digit0: bool) (digit1: bool) (digit2: bool) (digit3: bool)
      (digit4: bool) (digit5: bool) (digit6: bool) (digit7: bool)
```

```
context comm-semiring-1
```

```
begin
```

```
definition of-char :: ⟨char ⇒ 'a⟩
```

```
  where ⟨of-char c = horner-sum of-bool 2 [digit0 c, digit1 c, digit2 c, digit3 c,
digit4 c, digit5 c, digit6 c, digit7 c]⟩
```

```
lemma of-char-Char [simp]:
```

```
  ⟨of-char (Char b0 b1 b2 b3 b4 b5 b6 b7) =
    horner-sum of-bool 2 [b0, b1, b2, b3, b4, b5, b6, b7]⟩
```

```

by (simp add: of-char-def)

73.2.2 Syntactic representation

Logical ground representations for literals are:

1. *0* for the empty literal;
2. *Literal b0 ... b6 s* for a literal starting with one character and continued by another literal.

Syntactic representations for literals are:

3. Printable text as string prefixed with *STR*;
4. A single ascii value as numerical hexadecimal value prefixed with *STR*.

86.1 Introduction

Records are isomorphic to compound tuple types. To implement efficient records, we make this isomorphism explicit. Consider the record access/update simplification $\alpha(\beta\text{-update } f \text{ rec}) = \alpha \text{ rec}$ for distinct fields α and β of some record rec with n fields. There are $n \wedge 2$ such theorems, which prohibits storage of all of them for large n . The rules can be proved on the fly by case decomposition and simplification in $O(n)$ time. By creating $O(n)$ isomorphic-tuple types while defining the record, however, we can prove the access/update simplification in $O(\log(n) \wedge 2)$ time.

The $O(n)$ cost of case decomposition is not because $O(n)$ steps are taken, but rather because the resulting rule must contain $O(n)$ new variables and an $O(n)$ size concrete record construction. To sidestep this cost, we would like to avoid case decomposition in proving access/update theorems.

Record types are defined as isomorphic to tuple types. For instance, a record type with fields $'a$, $'b$, $'c$ and $'d$ might be introduced as isomorphic to $'a \times ('b \times ('c \times 'd))$. If we balance the tuple tree to $('a \times 'b) \times ('c \times 'd)$ then accessors can be defined by converting to the underlying type then using $O(\log(n))$ *fst* or *snd* operations. Updaters can be defined similarly, if we introduce a *fst-update* and *snd-update* function. Furthermore, we can prove the access/update theorem in $O(\log(n))$ steps by using simple rewrites on *fst*, *snd*, *fst-update* and *snd-update*.

The catch is that, although $O(\log(n))$ steps were taken, the underlying type we converted to is a tuple tree of size $O(n)$. Processing this term type wastes performance. We avoid this for large n by taking each subtree of size K and defining a new type isomorphic to that tuple subtree. A record can now be

defined as isomorphic to a tuple tree of these $O(n/K)$ new types, or, if $n > K * K$, we can repeat the process, until the record can be defined in terms of a tuple tree of complexity less than the constant K .

If we prove the access/update theorem on this type with the analogous steps to the tuple tree, we consume $O(\log(n)^2)$ time as the intermediate terms are $O(\log(n))$ in size and the types needed have size bounded by K . To enable this analogous traversal, we define the functions seen below: *iso-tuple-fst*, *iso-tuple-snd*, *iso-tuple-fst-update* and *iso-tuple-snd-update*. These functions generalise tuple operations by taking a parameter that encapsulates a tuple isomorphism. The rewrites needed on these functions now need an additional assumption which is that the isomorphism works.

These rewrites are typically used in a structured way. They are here presented as the introduction rule *isomorphic-tuple.intros* rather than as a rewrite rule set. The introduction form is an optimisation, as net matching can be performed at one term location for each step rather than the simplifier searching the term for possible pattern matches. The rule set is used as it is viewed outside the locale, with the locale assumption (that the isomorphism is valid) left as a rule assumption. All rules are structured to aid net matching, using either a point-free form or an encapsulating predicate.
